SUMMARY

PROBLEM

Develop a computer model for calculating the vertical and horizontal directionality of low-frequency ambient noise for an ocean environment.

RESULTS

A FORTRAN computer model has been developed. The Research Ambient Noise Directionality Model (RANDI) has given results in good agreement with measured data for the Pacific, Atlantic, and the Mediterranean.

RECOMMENDATIONS

RANDI noise calculations should be compared with ambient noise measurements for other ocean areas, seasons, and noise-source distributions as data, sufficiently documented for validation purposes, become available.

13. ABSTRACT A computer model for calculating the vertical and horizontal directionality of ambient noise and some of the results which have been obtained are discussed. The model considers three sources of surface-generated anisotropic noise, one source of surface-generated isotropic noise and two sources of volumetric isotropic noise. Noise levels are obtained for various propagation conditions and for different sensor depths. Results agree well with experimental data, and it is shown that the model can be a useful tool in the planning of ambient noise measurement experiments and in the analysis of results.

INTRODUCTION

The Research Ambient Noise Directionality Model (RANDI) is an operating general-purpose FORTRAN Program that calculates and displays, via CALCOMP plots, the vertical and horizontal directionality of low-frequency (between 10 and 500 Hz) ambient noise for an ocean environment. This first-phase program will be used in the design of ambient noise measurement experiments and in surveillance systems analysis studies. A variable-dependent approach based on system and environmental parameter variance makes this model inappropriate for synoptic forecasting. It will be improved and validated as time, data, and state-of-the-art permit.

BACKGROUND

The ambient noise at any particular point in the ocean depends upon the amount and location of noise-generating sources and the nature of the local acoustic propagation conditions, i.e., how the noise gets from the generator to the measuring sensor.

Sound in the ocean travels in curved or refracted paths and will arrive at a hydrophone from various vertical angles, depending on the depth of the source and the hydrophone and on the separation range. The path an individual sound ray travels can include surface reflections and bottom bounces, as illustrated in the ray diagram (Fig. 1). The bottom bounce paths will generally have the highest sound energy losses, while the paths which do not make contact with either the surface or the bottom will have the smallest transmission losses. The vertical angle between one of these latter rays and the horizontal is generally less than 15 deg at any range, while the rays making contact with the surface or bottom can have vertical angles approaching 90 deg. This effectively divides the sound rays into three distinct groups: (1) rays which come in contact with the bottom and arrive at angles from approximately 15 to 90 deg down from the horizontal; (2) the near-horizontal or SOFAR Channel rays, which touch neither surface nor bottom and, (3) the rays arriving at angles above 15 deg and which originated or were reflected from near the surface.

There are many sources of noise, the most important being winds, waves, shipping, thermal agitation and biological and seismic activity. The noise due to winds, waves, and shipping originates near the surface and arrives at the sensor along paths which travel near or reflect from the surface. In the case of distant sources, the noise travels by way of the SOFAR Channel and will arrive, at a sensor located within the channel, from nearly horizontal angles. Noise from near sources (within a few hundred miles) will arrive at angles closer to the vertical than does the SOFAR Channel noise. Thermal noise comes from throughout the medium and can arrive at any angle or from any direction. Seismic noise would be expected to arrive along those paths which come in contact with radiating or reflecting surfaces, including the bottom and distant seamounts. Biological noise, however, originates along the surface, the bottom, and throughout the medium.

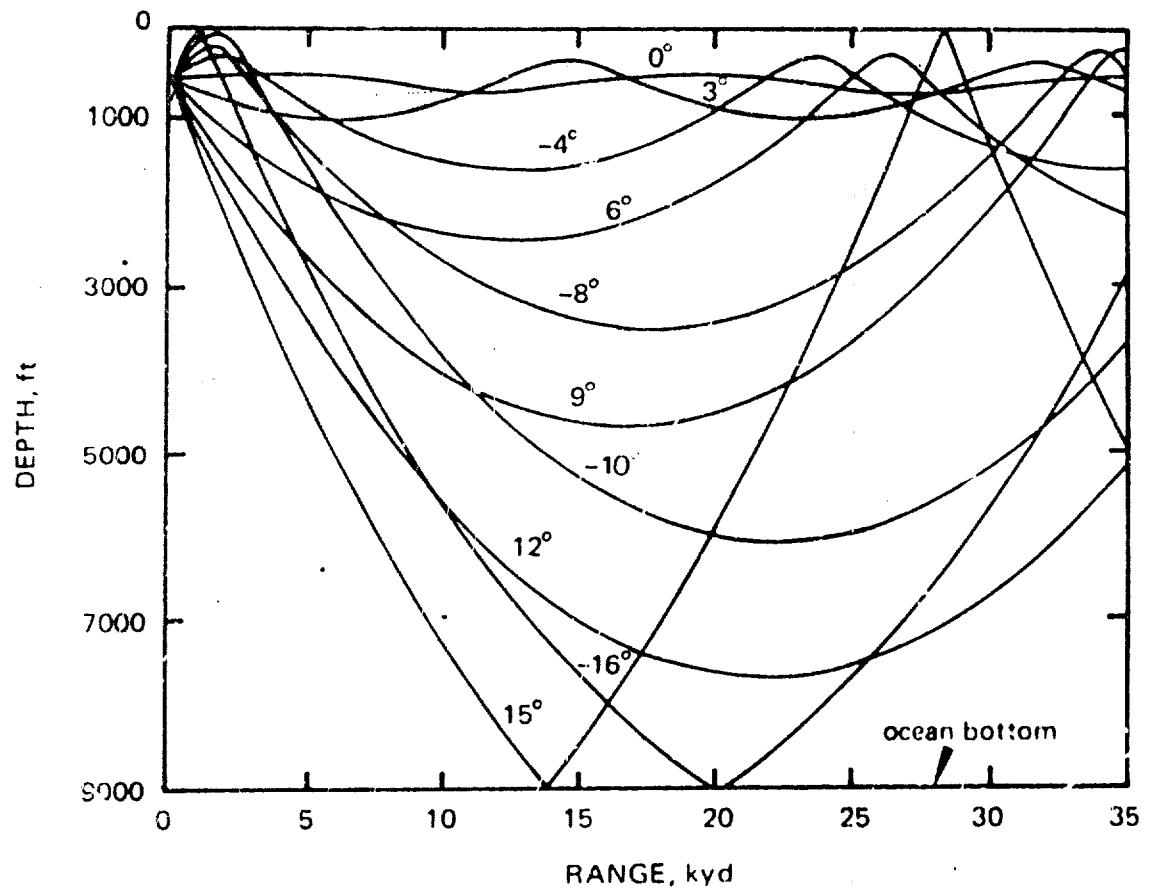

Figure 1. Typical raytrace diagram.

The net effect of propagating—to the sensor—the noises from such a highly stratified distribution of noise generators is a noise field having vertical directionality, i.e., noise level dependent on vertical arrival angle, as illustrated in Fig. 2.

Various ambient noise models have been proposed which include part of the major noise sources and invoke certain simplifying assumptions to produce a medium less hostile to mathematical description in an attempt to render the problem solvable and yet obtain meaningful results. Few investigators have succeeded, and then only in highly specialized cases. There is documentation on several of these ambient noise directionality models. In the opinion of the author, none is adequate for use in the design of detailed directional noise measurement experiments or for use in surveillance systems analysis studies. Miller (Ref. 1) and Urick (Ref. 2), for example, proposed theoretical models which require a zero sound-speed gradient. These models cannot account for surface-generated noise arriving at angles below the horizontal or for bottom noise (biological, seismic) arriving at angles above the horizontal, except by reflection from the bottom or surface, respectively. This results in a distorted directional noise pattern with abnormally low levels near the horizontal. Talham's model (Ref. 3), on the other hand, includes realistic sound-speed profiles but applies only to bottom-mounted hydrophones. Bartberger (Ref. 4) considered only ship

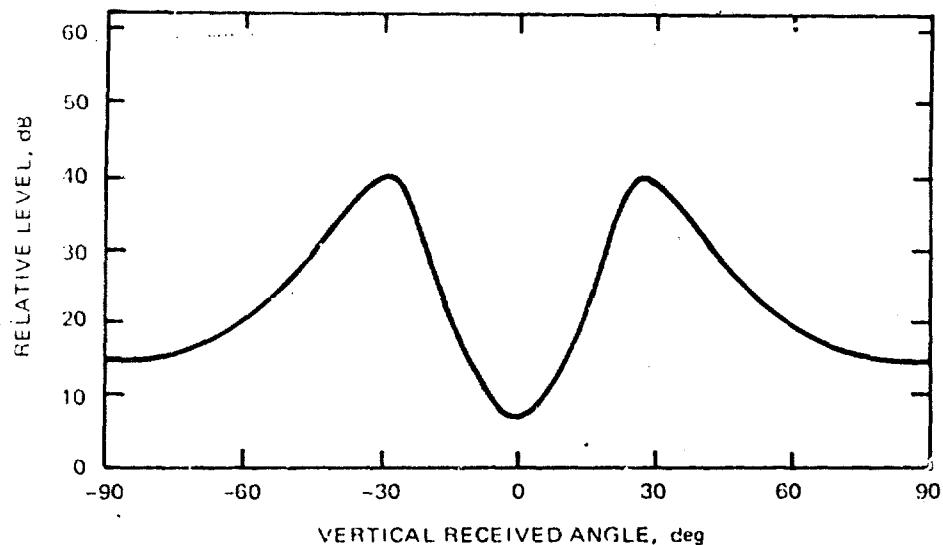

Figure 2. Typical ambient noise vertical directionality plot.

noise from a uniform distribution of surface ships, thus restricting the usefulness of his model to the 20- to 100-Hz region. Finally, the MOSS Ambient Noise Model developed jointly by the Navy and Bell Telephone Laboratories calculates the expected vertical directionality of the noise field for seven ocean areas for the mean summer and winter conditions for acoustic propagation, wind speed, and shipping. A more general area-independent model is desired.

In addition to the limitations already discussed, none of the above models considers horizontal directionality, noise due to distant sources (SOFAR Channel noise), or noise of a biological or transient nature, nor does any contain sufficient provision for considering variations in system characteristics. For these reasons RANDI was developed for use in the design of ambient noise measurement experiments and the analysis of surveillance systems.

AMBIENT NOISE DIRECTIONALITY MODEL

MODEL DESCRIPTION

RANDI utilizes one or two of three different sources for the propagation loss between the noise generators and the sensor. The first source is a self-contained linear raytrace routine, one which approximates the sound-speed profile by a series of straight-line segments and corrects for earth curvature. See Ref. 5 for a detailed description.

The second source is a set of propagation loss versus range and arrival angle arrays which is input as data. If the propagation loss is input, RANDI will bypass the raytrace routine. Hence, ambient noise calculations by RANDI can be based on propagation loss values from ray theory (its own or nearly any other raytrace model, including those that account for variable bottom topography and horizontal changes in the sound-speed profile),

normal-mode theory, experimental measurements, or any method by which propagation loss versus range and arrival angle might be obtained. This second source of propagation loss can be extremely useful when operating RANDI at the relatively low frequencies of many passive surveillance systems, where the validity of ray theory becomes questionable and normal-mode theory more attractive.

The third form of propagation loss utilized by RANDI is for sound energy traveling from distant sources to a sensor located within the SOFAR Channel. RANDI calculates the propagation loss in this case by considering the effects of frequency-dependent attenuation and spreading loss increasing with fifteen times the log of the average range to the continental shelf or the range to where the SOFAR Channel reaches the surface (as in northern latitudes).

In addition to distant noise, RANDI considers five other sources of isotropic and anisotropic surface and volumetric noise (Fig. 3): shipping, sea state 0, biological, rain, and wind-wave interaction.

The surface noise is generated by an infinite number of point sources distributed along a horizontal "noise source plane" just below the surface (Fig. 4). The depth of this plane is set at 20 ft, since the main ship noise radiators (screws, shaft, and hull) are near this depth, and surface wave action extends well below the surface. The shipping noise generators are nonuniformly distributed, while the wind-wave and rain noise generators are uniformly distributed. The noise resulting from any of these three sources is anisotropic. Sea state 0 and biological noises come from a uniform volumetric distribution of noise generators centered around the sensor and result in isotropic noise. The SOFAR Channel noise received by a sensor located within the SOFAR Channel is also isotropic for all channeled ray angles. The total noise field, then, is part isotropic and part anisotropic.

A target capability is also included in RANDI. By specifying the oceanographic, environmental and noise conditions, and a target location, depth, and frequency spectrum or line component, the Surveillance System Analyst receives, by way of plot and printed output, the levels and angles of target multiple arrivals superimposed on the ambient noise arrivals (see Figs. B-4 through B-13). Such a capability can make RANDI a useful tool in the design, analysis, and optimization of surveillance systems.

MATHEMATICAL DESCRIPTION

The anisotropic shipping noise squared pressure spectrum level SNL (for a 1-Hz band) in the model is obtained from surface noise generators which have a radiated sound pressure level varying with frequency. The following empirical expression, which has characteristics similar to the spectra given in Fig. 71 of Ref. 6, is utilized:

$$\begin{aligned} \text{SNL (re } \mu\text{Pa)} = & A_0 - 10 \log (10^{-1.0 \log f' + 1.16} + 10^{+3.3 \log f' - 6.27}) \\ & + 4 \text{ SHIPD} + 50 \log (\text{SPEED}/12) + 20 \log (\text{LENGTH}/300) \end{aligned}$$

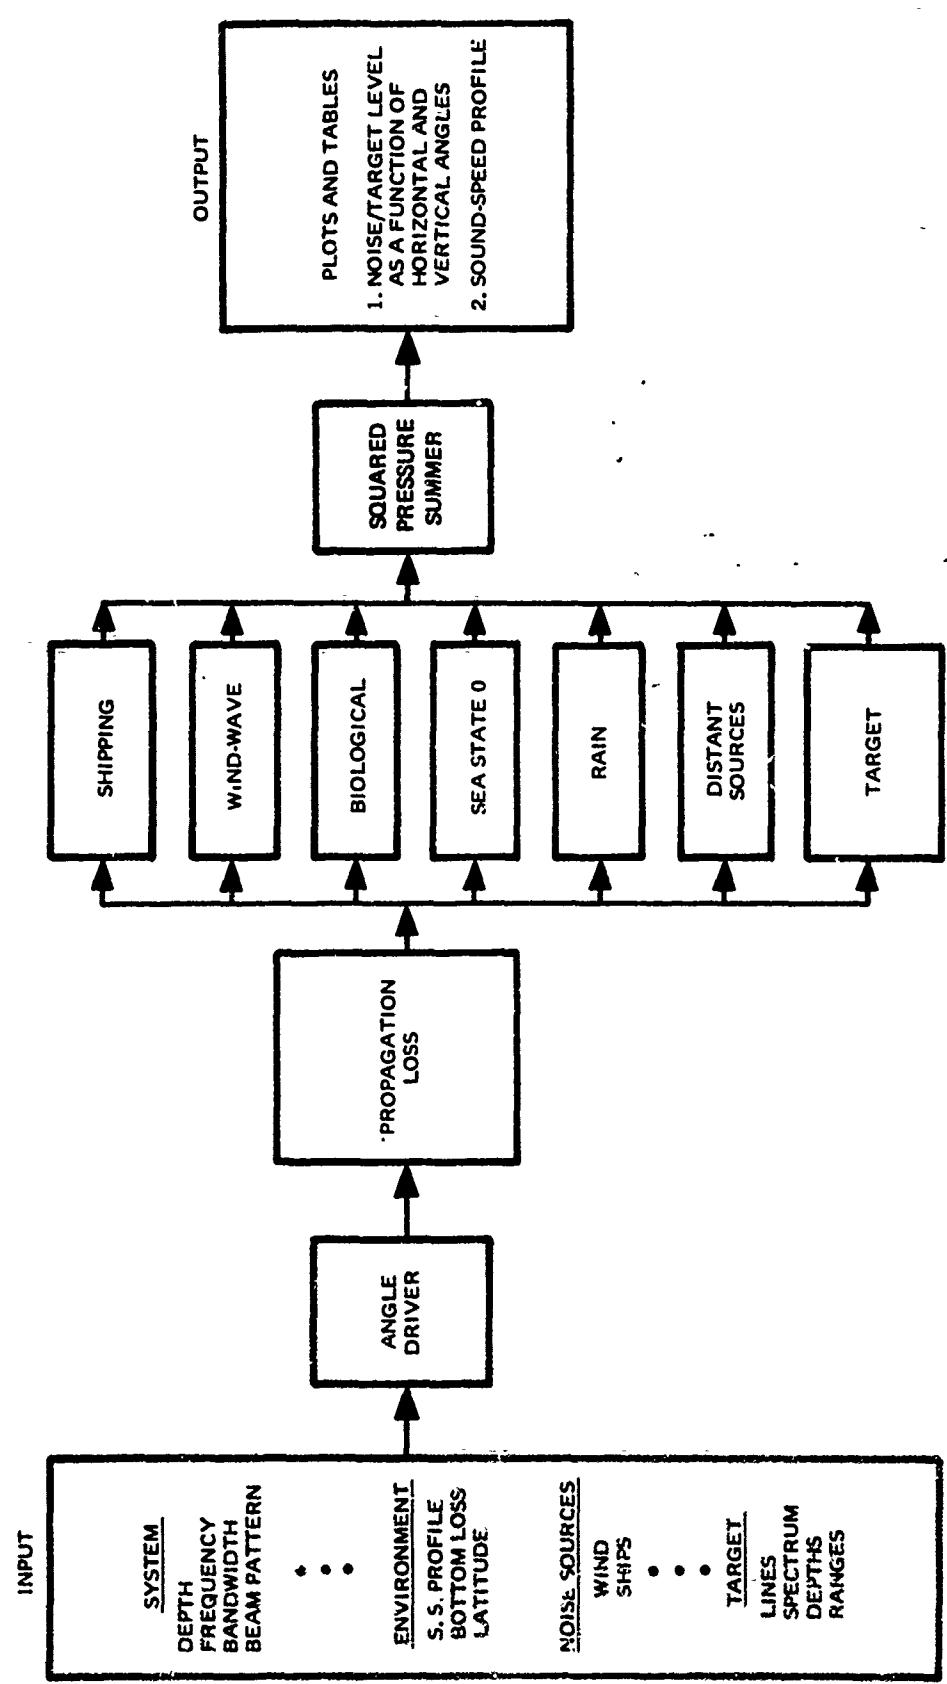

Figure 3. RANDI model block diagram.

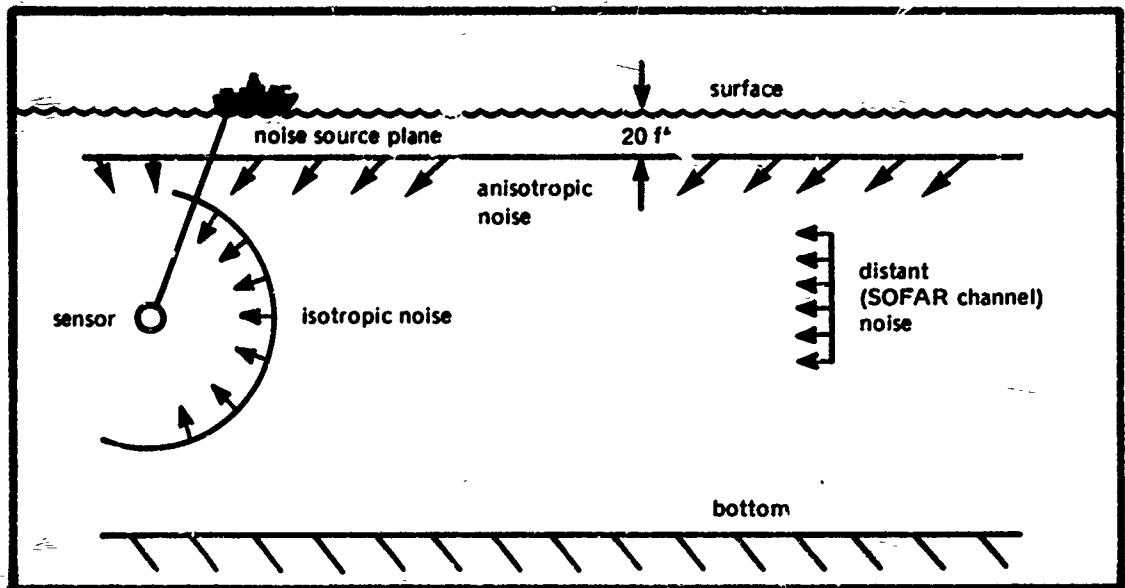

Figure 4. RANDI model noise field.

where

$$A_0 = \begin{cases} 90 & \text{no distant noise sources} \\ 85 & \text{distant noise sources specified} \end{cases}$$

$$f' = f - 2 \text{ SHIPD} + 12$$

f = number of hertz

SHIPD = shipping density indicator (0 - 7)

SPEED = number of knots of noise-source ships' average speed

LENGTH = number of feet of noise-source ships' average length

The squared pressures obtained from the levels given by this function are distributed over the noise source plane in such a way to result in effective squared pressures for unit area at unit distance (the mechanics are described in the section on model calibration) with magnitude varying in range and azimuth in such a manner to be proportional to the density of an input shipping density distribution ASHIP (ship density vs range array) or a shipping density indicator SHIPD (no shipping to heavy shipping on a scale from zero to seven). A similar expression was used for the squared pressure level due to distant sources DSL, since shipping is the major contributor at low frequencies and the higher frequencies are severely attenuated at SOFAR Channel propagation ranges.

The squared pressure spectrum levels for the anisotropic noise WNL due to wind-wave interaction were obtained from a fit to the data of Perrone (Ref. 7) and are a function of wind speed and frequency as follows:

$$\text{WNL (re } \mu\text{Pa)} = -18 \log f + 96$$

$$+ [9.66 (\log f)^2 - 26 \log f + 27.3] (0.065 \text{ WSPD}^{0.7})$$

where WSPD = number of knots of wind speed in the vicinity of the sensor.

These levels are converted into mean squared sound pressure in a 1-Hz band and further modified by a multiplying factor to achieve directionality of the source at high frequencies and nondirectionality at the lower frequencies as indicated by Becken (Ref. 8). The wind noise squared pressure modifier used in the model is the following:

$$\text{Squared pressure multiplier} = 1 - (1 - \cos^n \phi) (0.002 f - 0.02)$$

where ϕ = angle (in degrees) from the vertical that the ray makes at the source, and

$$n = \begin{cases} \frac{90 - \phi}{10} & 0 \leq \phi \leq 70 \\ 2 & 70 \leq \phi \leq 90 \end{cases}$$

The following function, obtained from the data of Franz (Ref. 9), gives, for rain, the expected noise squared pressure level RPL in a 1-Hz band and is distributed uniformly along the horizontal noise plane in a manner similar to the wind-wave noise.

$$\text{RPL (re } \mu\text{Pa)} = 5.5 \log f + 50.5 + 14.5 \log (\text{RAIN})$$

where RAIN is the number of inches of rainfall per hour in the vicinity of the sensor.

Isotropic sea state 0 noise squared pressure spectrum level SSO is that noise which is measured under the ideal conditions of no wind, calm surface, no biological activity, and negligible shipping. It varies with frequency and is independent of depth and geographic location. The equation for SSO (for a 1-Hz band) was obtained by a quadratic fit to data of Wenz (Ref. 10):

$$\text{SSO (re } \mu\text{Pa)} = 4.22 (\log f)^2 - 33.4 \log f + 89.1$$

A volumetric or isotropic distribution was chosen for biological noise in the absence of data indicating otherwise. This noise varies with time of day and relative amount of activity expected at a particular site. An activity indicator on a scale from zero to ten is an input to the model. The equation for the biological noise squared pressure spectrum level BPL is of the following form:

$$\text{BPL (re } \mu\text{Pa)} = 0.00175 (100 - f) \sin [0.00262 (\text{hr} - 300)] \text{ ACTIVITY}$$

$$- 16.96 (\log f)^2 + 50.1 \log f + 45.1$$

where the $0 \leq \text{ACTIVITY} \leq 10$ and hr is the local time of day (military designation 0000-2400).

The sound pressure spectrum level TSL for a target source is accepted by the model by reading in the appropriate coefficients A_i , $i = 1, 3$, of a third-degree polynomial

$$TSL = A_3 (\log f)^3 + A_2 (\log f)^2 + A_1 \log f + A_0$$

In the event that the line component is the dominant feature in the band of interest, A_0 is the level of the line. Also specified by the user are the initial target range and depth, the numbers of target ranges and depths to be calculated, and the increments in range and depth to be used.

COMPUTATIONAL PROCEDURE

All of the noise and target squared pressure spectrum levels are integrated over a user-specified bandwidth by means of an input frequency response function. If none is specified, a 1-Hz bandwidth and a constant bandpass frequency response function are assumed.

The squared pressure received for a differential vertical angle is obtained by first calculating the area defined by the intersections of the corresponding ray bundle with the noise source plane. These areas are multiplied by the local effective squared noise pressures for unit area at a distance of 1 yard. The resulting squared pressures are then reduced to account for propagation loss and summed. To this value is added the contribution of the isotropic noise sources. The result is further reduced to account for the vertical response of an individual hydrophone or an array of hydrophones. If no response function is specified, it is assumed omnidirectional. The final squared noise pressure arriving at that angle is stored for output and the process is repeated for an adjacent ray bundle at a new vertical angle.

In the case where horizontal directionality is desired, the ocean is divided into n regions by passing vertical planes through the sensor location at $360/n$ deg. The ocean is then effectively divided into n regions, similar to a huge sliced pie of infinite radius whose thickness is equal to the ocean depth at the receiver location. The pertinent environmental and noise parameters are specified separately for each "pie slice" region. Hence, the calculations performed for one region are independent of the calculations performed in adjacent regions. The total squared noise pressure, that which would be measured by an omnidirectional hydrophone, is obtained by summing the squared noise pressures for the n independent "pie slice" regions. An example is given in Appendix B, Figs. B-6 through B-11.

An explanation of terminology used in the ambient noise directionality illustrations is necessary before results can be interpreted. Noise level refers to the per steradian mean squared pressure spectrum level. Vertical received angle is the angle at the sensor the incident ray makes with the horizontal. The negative rays are downcoming rays at the sensor, with the ray having a vertical received angle of -90 deg being the ray which arrives from

the surface directly above the sensor. The rays with positive angles arrive at the sensor from angles below the horizontal.

Unlike noise, targets are treated as point sources at specific ranges and depths. However, the received signal squared pressures are similarly influenced by the bandwidth, frequency response function, and the vertical beam response function.

To aid the user, many of the model inputs have been initialized in data statements. This eliminates the repeated input of variables which are common to many situations and yet allows the initial values to be suppressed in the event that different values are desired. Those parameters which have been initialized are given in the model input section of the program listing, Appendix C.

MODEL CALIBRATION PROCEDURE

The functional relationships used for noise express the pressure spectrum levels one would expect to measure and are not source levels. To get the effective source levels at a distance of 1 yard (for unit surface area) for distributions of noise generators requires removing from the original levels the effects of frequency-dependent attenuation in the medium and then normalizing to a unit of surface area. This is accomplished by distributing the noise generators along the horizontal noise plane and propagating the noise at different frequencies. A calibration function can then be obtained which is added to the original levels to yield corrected levels and eliminate bias. This effectively removes the effects of frequency attenuation in the original levels and converts them to source levels for unit surface area. Finally, the output of the model is adjusted to coincide with measured data for one set of conditions (frequency, depth, wind speed, etc.) at one location.

This calibration is dependent on the manner in which the noise sources are distributed and the method by which the noise generation area is calculated and is independent of the medium. Hence, once this calibration is performed for one set of conditions at one location, it need not be done for other conditions or locations. The initial calibration was performed using Marine Physical Laboratory (MPL) Pacific ambient noise data (Ref. 11) and shipping information provided by Western Seas Frontier.

MODEL VALIDATION

The final step, validation, has not yet been completed. This requires comparing the model output with measured data for many different locations, seasons, depths, frequencies, shipping distributions, wind speeds, etc. Tentative plans include comparing with the IOMEDEX data, which were taken in the Mediterranean during November 1971. Comparison with other data sets for different conditions will be done as data become available. Although a large quantity of data is now readily available, the lack of shipping information for the time interval during which the measurements were taken disqualifies it. Nearly all historical ambient noise data are inappropriate for model validation.

DISCUSSION OF RESULTS

GENERAL RESULTS

Examples of output from the model for three different geographic locations (Fig. 5) have been included to illustrate both the capability of the model and variability in the directional character of the noise field resulting from differences in sensor depth and acoustic propagation (Figs. 6, 7, and 8). Profiles which generally characterize summer conditions in the Pacific, Atlantic, and Mediterranean were chosen.

It is interesting to note the existence of the trough (low level of noise) in the noise field near the horizontal. This condition results from the horizontal rays at the hydrophone

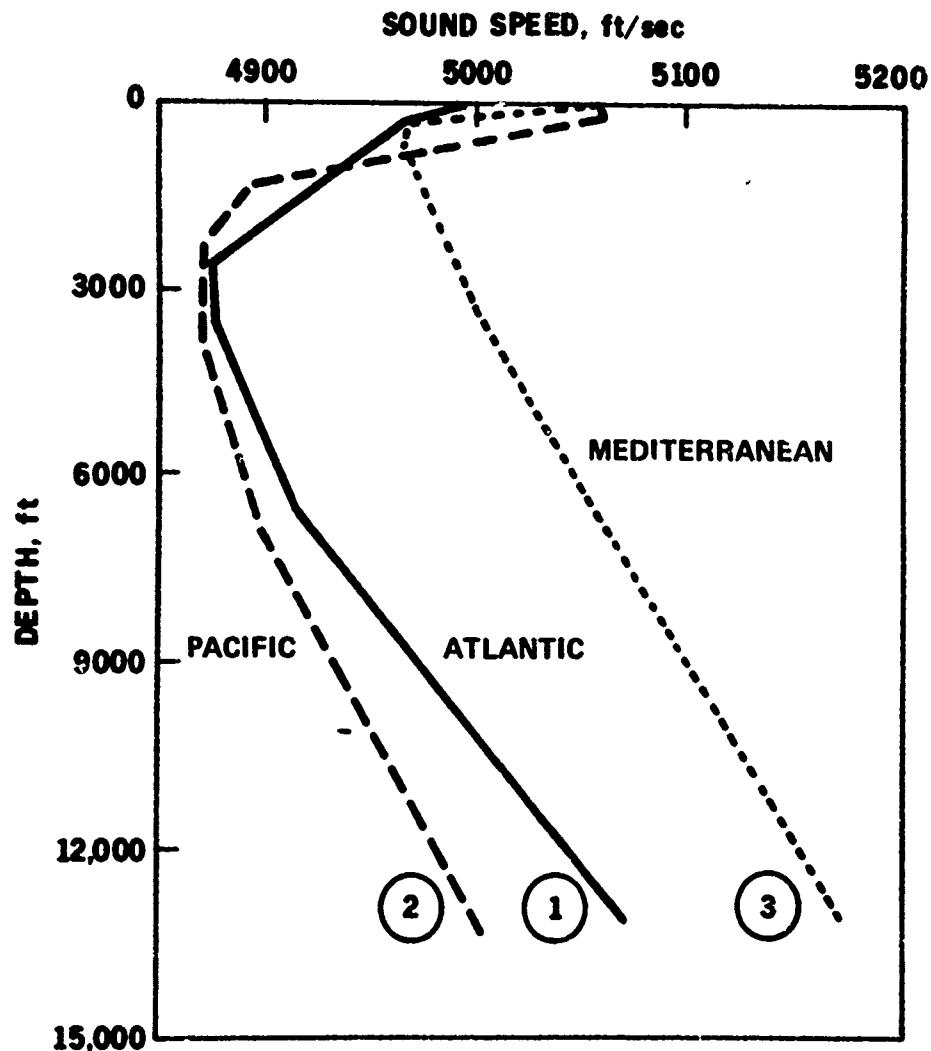

Figure 5. Sound-speed profiles for Areas 1, 2, and 3.

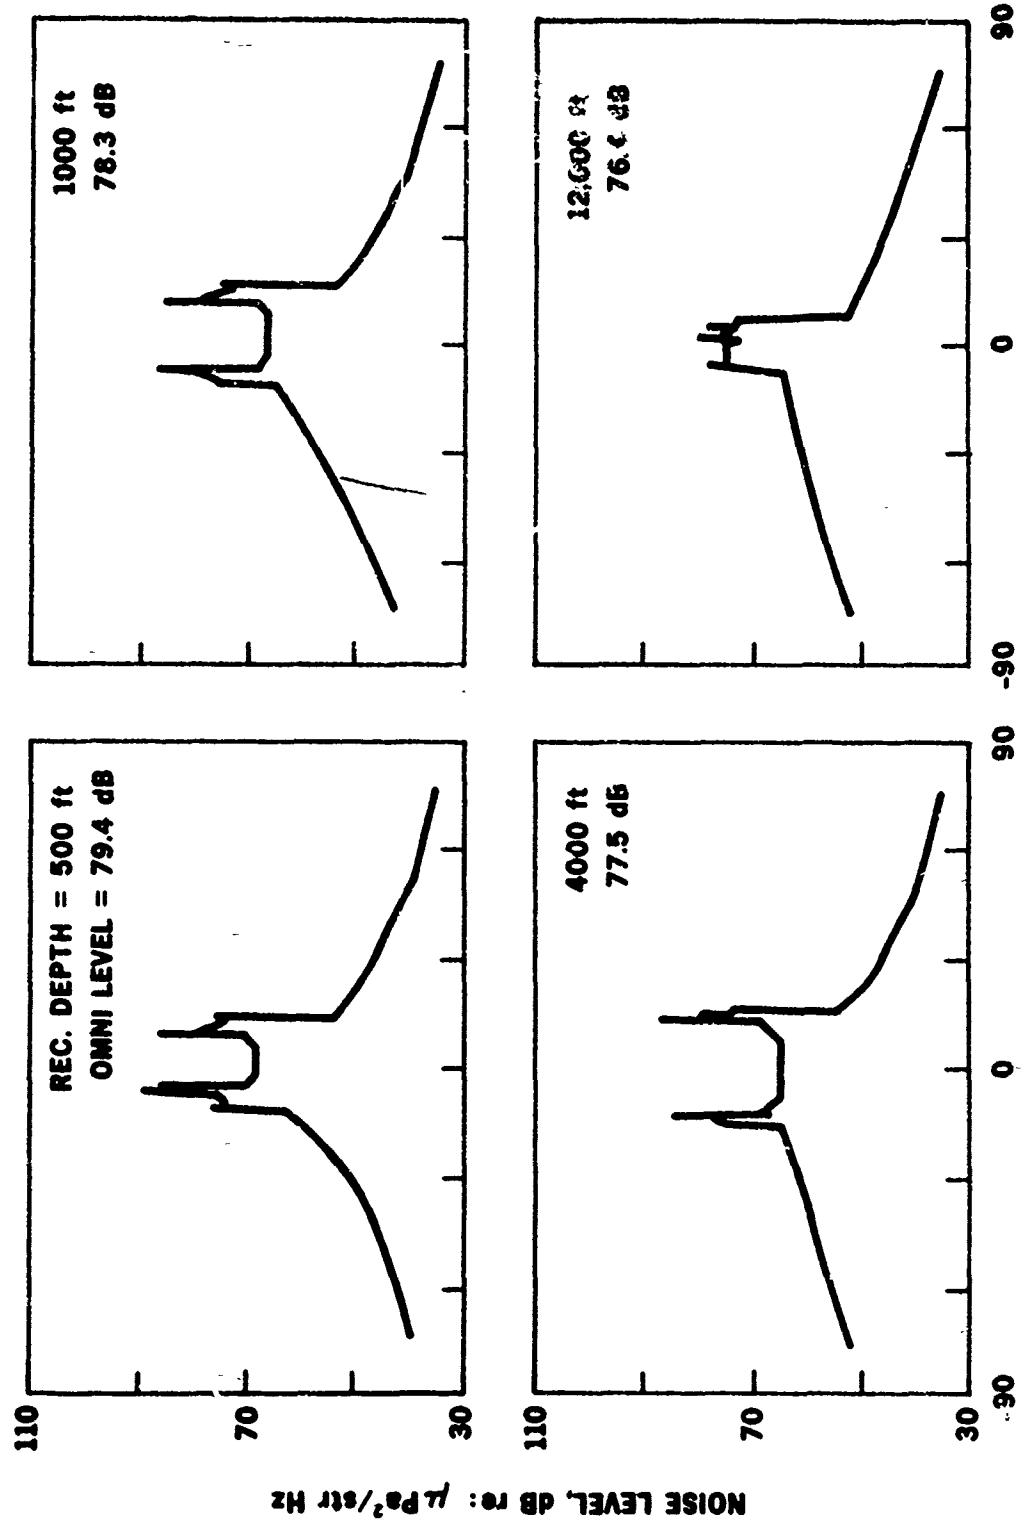

Figure 6. Vertical directivity of ambient noise at four different depths for Area 1.

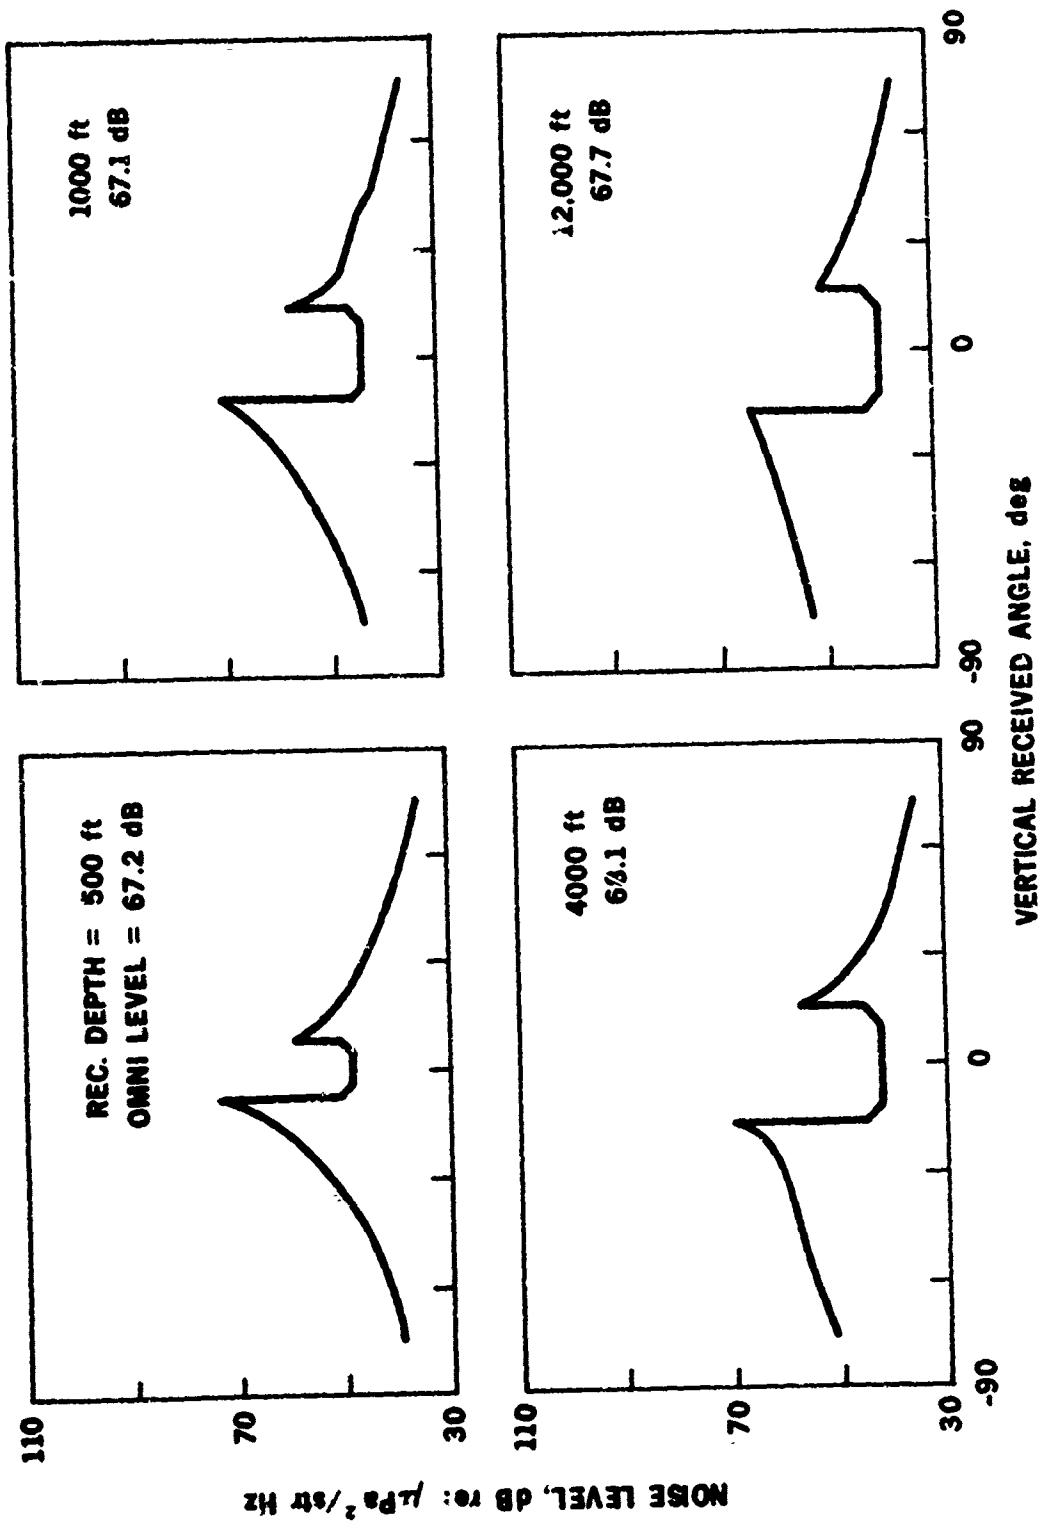

Figure 7. Vertical directivity of ambient noise at four different depths for Area 2.

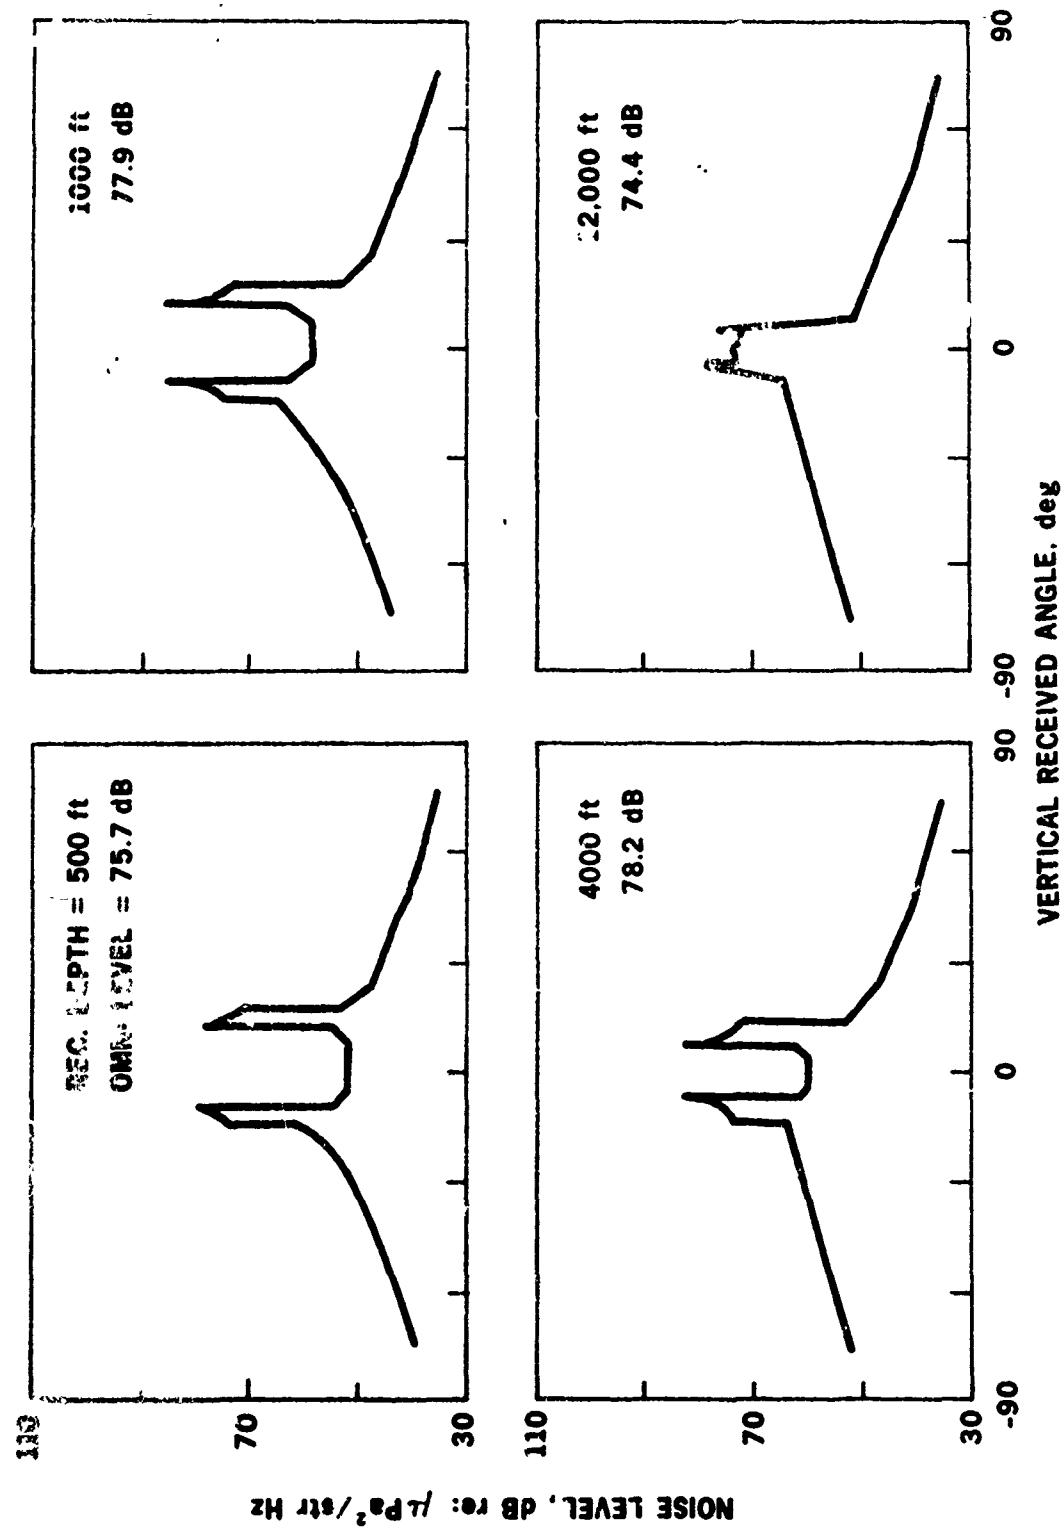

Figure 8. Vertical directivity of ambient noise at four different depths for Area 3.

being unable to reach the surface, where the wind and shipping noise is generated. In two cases, as the depth increases, the trough becomes narrower and eventually disappears, indicating that only near the bottom will the horizontal rays "see" the surface. In the other case, however, the trough gets wider as the depth increases. This results from the sound speed at the bottom being much less than that at the surface; hence, horizontal bottom rays can never reach the surface. Energy within the trough arrives from distant sources. The trough levels are determined by the amount of energy which has become trapped within the SOFAR Channel. There can be a trough, or it can be filled in, depending on whether the energy per arrival angle due to near sources is greater or less than that due to distant sources. The total amount of sound energy received from the distant sources depends on the total number of ships over the continental slope and shelf, range to the shelf, and the total channel "look" angle at the sensor depth.

The lower level of sound at down going angles, greater than approximately 15 deg, compared to the up going angles, less than -15 deg, results from bottom loss. The upcoming rays, having bounced off the bottom before reaching the receiver, suffer a loss in energy not experienced by rays coming from the surface. This accounts for the asymmetric shape of the noise plots.

MODEL OUTPUT-MEASURED DATA COMPARISON

Ambient noise data obtained by MPL (Ref. 11) during their April and May 1971 FLIP ambient noise measurements were utilized for the initial model calibration and to perform a level-variable dependence check.

The model was initially calibrated at 50 Hz and 100 m receiver depth by reading in the measured wind speed and recorded shipping data and adjusting the model output to correspond to the measured noise level for a single day of the 15-day series of measurements. The output of the model was then compared with the measured data for other frequencies, depths, wind speeds and shipping distributions.

Figures 9a and b are examples of how RANDI compares with the MPL data as a function of time. Only every other point of the original MPL data (one each day) has been retained to compare with the model, since the shipping distribution near the FLIP site was reported only once each day. Figure 9a is a comparison of the MPL data and the RANDI output for 200 Hz at 560 m receiver depth. This frequency is of particular interest in checking the output of the model, since, at this frequency, both shipping and wind-wave interaction make significant contributions to the total noise level. This figure indicates that the model is, in general, within 2 or 3 dB of the measured data. The anomalous results can be explained by the presence or lack of nearby (within the same 1-deg square as FLIP) shipping which was reported (erroneously perhaps) but was not seen by FLIP personnel or could have been close to FLIP's position but not reported. The agreement at 400 Hz (Fig. 9b) is similarly encouraging for such a rough initial calibration.

Figure 9c compares the noise levels calculated for MPL by CAPT Paul Wolff (Ref. 11) using two different noise models, the noise as calculated by RANDI and the

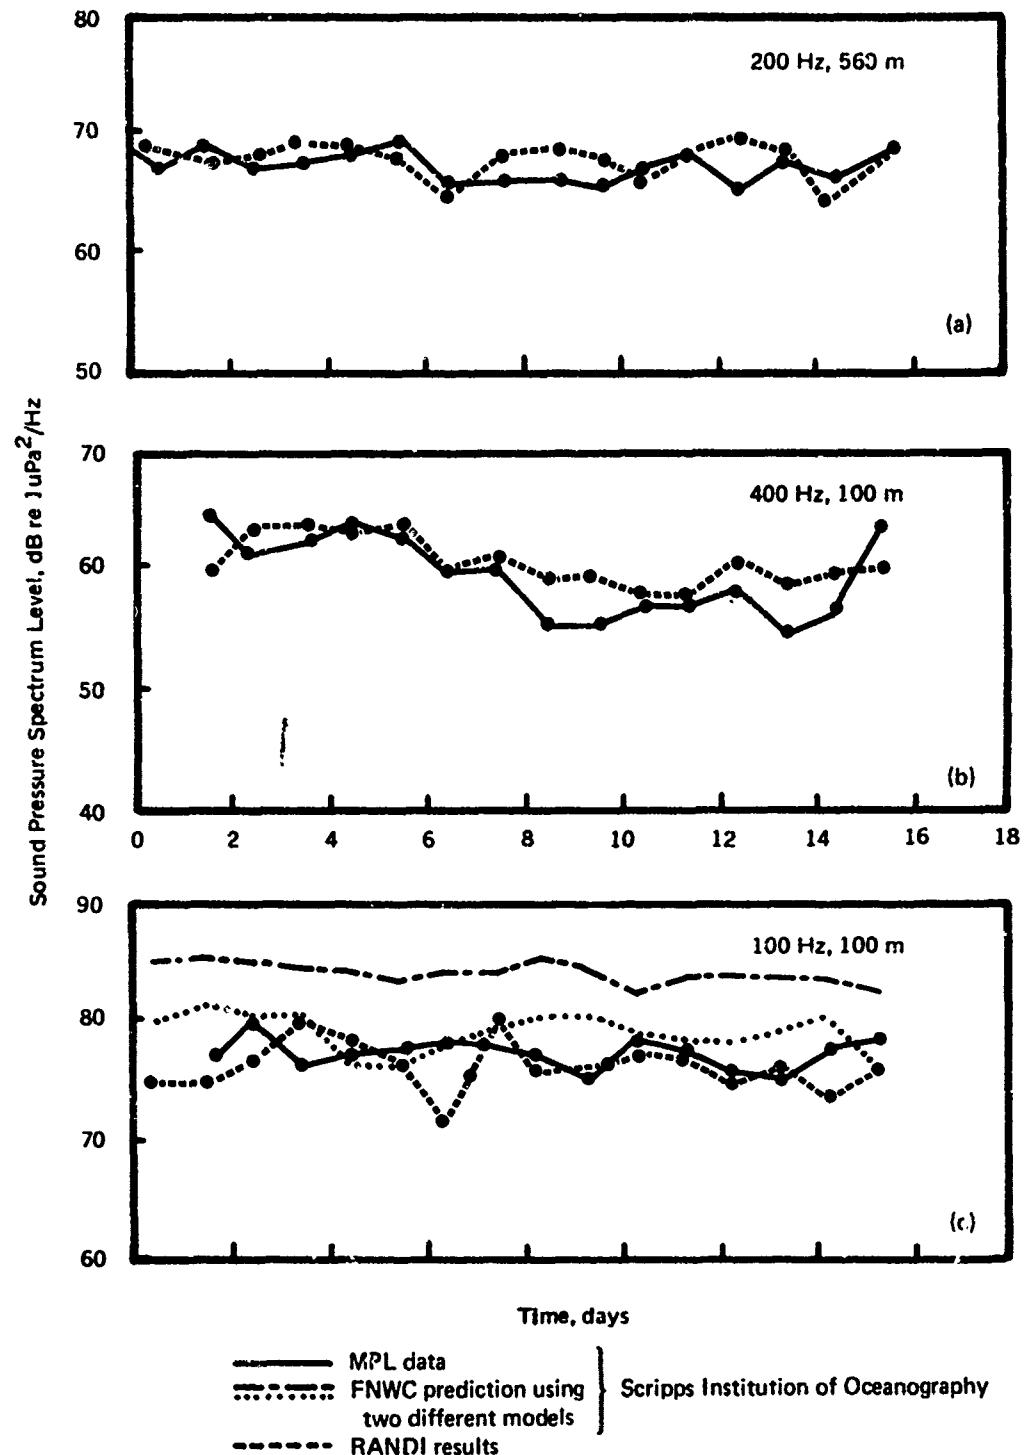

Figure 9. RANDI model-measured data comparison for several frequencies and depths (Ref. 11).

MPL data for 100 Hz at 100 m depth. Again the agreement between RANDI and the MPL data is good.

RANDI also indicated that the noise field should have a depth dependence. The total reduction in noise level as the sensor depth increased from 100 to 3930 m was calculated to be 6 dB at 50 Hz and 4 dB at 400 Hz. The data, however, showed a reduction of about 10 and 4 dB, respectively, for the same conditions. The discrepancy at 50 Hz is largely attributable to not specifying distant (SOFAR Channel) noise sources in RANDI when the comparisons were made. This could easily add the required 4 dB, since the total SOFAR Channel "look angle" at the axis is approximately 22 deg and the nearby shipping was relatively light. A similar depth dependence was observed by Lomask and Frassetto in the Mediterranean, where they utilized the bathyscaphe *Trieste* (Ref. 12). Weigle and Watt (Ref. 13), however, generally observed less than 3 dB depth dependence in the Mediterranean for the same frequency range. The environmental and shipping data from Ref. 13 were used as input for RANDI to enable comparison with the measured data. The results are presented in Table 1. Since the data are classified, only the differences in the measured and calculated (by RANDI) levels are given as a function of frequency and depth. It is interesting to note that although RANDI was calibrated with Pacific data, where the ambient noise levels are about 20 dB less than in the Mediterranean, RANDI calculated the Mediterranean noise within about 1 or 2 dB.

RANDI was also used to obtain the horizontal directionality of the ambient noise for one shipping distribution and wind speed during the FLIP ambient noise measurement program. The results are given in Figs. B-6 through B-11.

FUTURE IMPROVEMENTS

Improvements in the current ambient noise directionality model will be made as time and state-of-the-art permit.

Transient noise, including noise from seismic disturbances and explosions, is of considerable interest and will be included in RANDI within the immediate future.

SUMMARY

RANDI is a working FORTRAN model which calculates and plots the directional character of low-frequency ambient noise in the ocean environment. This model is conceptually simple and will be improved as time and state-of-the-art permit. It is intended to be a tool to aid in the design of noise measurement experiments and in surveillance systems design and evaluation and not for ambient noise synoptic forecasting.

RANDI SUBROUTINE DESCRIPTIONS AND FLOW DIAGRAM

Figure A-1 illustrates how the main or executive routine controls the flow of logic through the 21 subroutines which comprise RANDI. This figure can also be used as a guide in "streamlining" RANDI by removing those subroutines which will not be required by the user. In such a case, "dummy" or "empty" subroutines are substituted for the originals. For example, RANDI could easily be loaded into a relatively small computer when the propagation loss versus range is to be read in and no sound-speed profile plot is required. This is accomplished by substituting "empty" subroutines for TARGET, RAPATH, SUMINT, RAYTRC, VERTEX, HSURF, SCLNCE and SS PLOT. If only a printout is desired, PLT could also be deleted.

The following is a brief functional description of each subroutine:

- ALFA** contains the equation for the absorption coefficient as a function of frequency and water temperature.
- AUXPR** calculates sea surface area intersected by a ray bundle and sums squared sound pressure when propagation loss is read in.
- BIO** contains equation for biological noise as a function of frequency, time and biological activity indicator.
- BWIDTH** integrates noise or target spectrum using an input bandwidth response function.
- ERTHC** corrects the sound speed profile to include the effects of earth curvature.
- FUNS** obtains the squared noise pressure from the shipping histogram array for a given range.
- FUNU** linearly interpolates between two points.
- HLOSS** computes absorption, spreading and refraction losses.
- HSURF** computes surface reflection losses.
- PLT** plots noise and target levels
- PRINTS** prints input and initial variables.

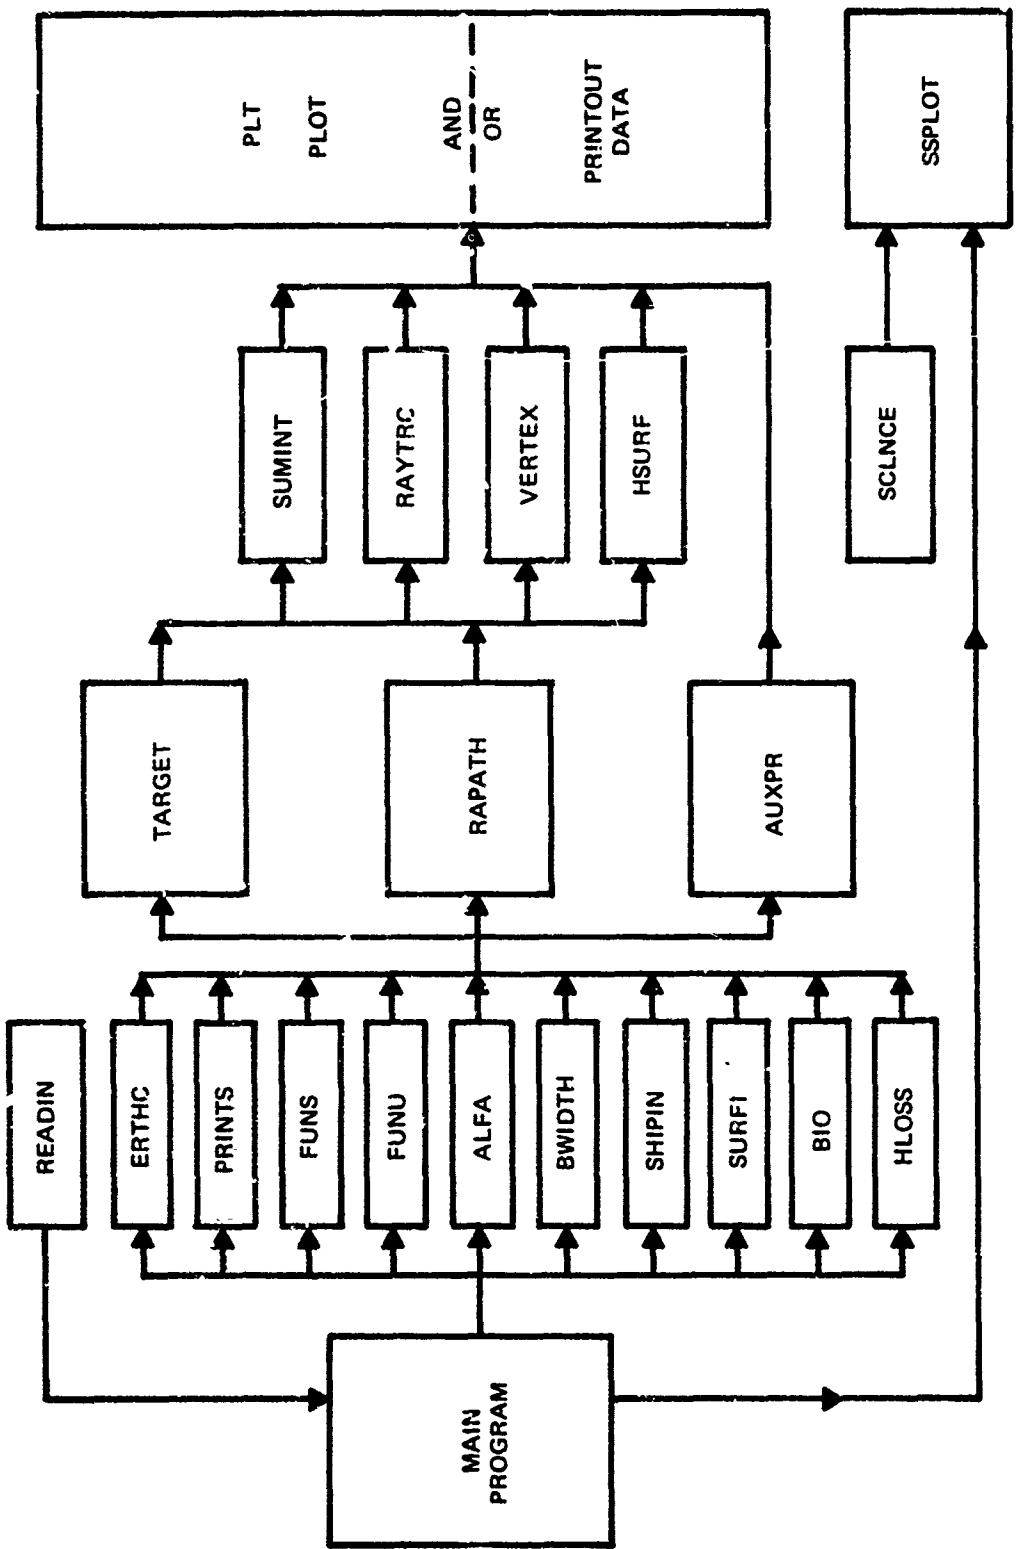

Figure A-1. RAND1 subroutine flow diagram.

RAPATH generates ray paths and corresponding propagation losses.

RAYTRC determines path taken by each ray.

READIN reads input parameters.

SCLNCE produces convenient set of scale numbers for sound-speed profile plot.

SHIPIN constructs the ray for the shipping noise squared pressure versus range histogram.

SSPLOT plots sound-speed profile.

SUMINT calculates sea surface area intersected by a ray bundle and sums squared sound pressure when propagation loss not read in.

SURFI contains the squared pressure levels for thermal, shipping, wind-wave and rain noise generators.

TARGET traces rays from target to sensor and computes received signal levels and arrival angles.

VERTEX computes greatest and shallowest depths reached by ray

Appendix B
RANDI INPUT-OUTPUT

RANDI INPUT DATA AND FORMAT

Input data cards for RANDI include parameter cards, array cards and run-control cards.

A RANDI input parameter card consists of an arbitrary number of parameter fields in free format. Each parameter field is separated by a comma, oblique, or blank space and contains the parameter name followed by an equal sign and then the value the parameter is to be assigned for that and subsequent consecutive runs or until a new value is assigned. The array cards contain the name of the array followed by an equal sign, which is immediately followed by the first value in the array. Subsequent values are separated by a blank space. Values which are continued on additional cards are preceded by an asterisk and a blank space at the beginning of the string of values contained on the continuation card.

Data cards for consecutive runs are separated by a PAUSE run control card, which signals the end of data for one run and that further data follows for another run. The last data set is followed by an END-DATA card signaling the end of data for the last run.

The PRLOSS card precedes each array of propagation loss versus range and follows the parameter and array cards for a given run but precedes the PAUSE card. The plot data cards follow the PAUSE card at the end of that data set for a given run, since they are read directly by the plot routines and not the READIN subroutine.

Although it is possible to read in a total of thirty-six parameters and arrays, RANDI can be run, for the large majority of cases, by merely reading in a few variables. For example, if only the sound-speed profile, frequency, and sensor depth are read in, RANDI will use preprogrammed values for the other variables and arrays in calculating the ambient noise. The preprogrammed values are listed in the model input section of the model listing of Appendix C. The resulting noise calculation, then, will be for the given depth, a wind speed of 5 knots, moderately heavy shipping, an omnidirectional vertical beam response function, and a 1-Hz bandwidth centered at the input frequency integrated over a bandpass frequency response function. A 360-deg horizontal sector width, moderate bottom loss, and a latitude of 40-deg will also be used.

The following is a list and brief description of the RANDI input variables and output products.

INPUTS

System

Name	Units	
ADANF	ARRAY	Frequency (kHz) and depth (ft) array
ZTG	FEET	Noise source depth
PHID	DEG	Declination-elevation angle

Name	Units	
DELPH	DEG	Vertical half-power beamwidth
DGREH	DEG	Width of horizontal sector
BERNG	DEG	Bearing of horizontal sector
BNCS		Number of ray bounces
ABW	ARRAY	Frequency response (dB down) across bandwidth
ARESP	ARRAY	Vertical beam response (dB down) pattern

ENVIRONMENTAL

ALAT	DEG	Latitude for earth curvature effects
AVELP	ARRAY	Sound-speed (ft/sec) vs depth (ft) profile
AHB	ARRAY	Bottom reflection loss (dB) vs grazing angle (deg)
APROP	ARRAY	Optional prop loss (dB) vs range (kyd) with elevation angle (deg) and ray bundle width (deg)

NOISE SOURCES

WSPD	KT	Wind speed in knots
ACTIV		Biological activity
HOUR	HR	Local time of day in hours (military)
RAIN	IN/HR	Rainfall
SHIPD		Ship density scale
ASHIP	ARRAY	Ship density (No./10000 sq mi) vs range (nmi)
SHLFR	NM	Average distance to continental shelf and surfaced sound channel
SHLFS		Number of ships within horizontal sector over continental shelf and in surfaced sound channel

TARGET

ZTG1	FT	Target depth
ZTGNO		Number of target depths
ZTING	FT	Target depth increment
RGT	KYD	Range to target
RGTNO		Number of target ranges
RGINC	KYD	Target range increment
TARG		If less than 0 TARG0 is a target line component in dB/micropascal, otherwise TARG0 is const in target spectrum level equation
TARG0		Level of line component in dB or const in spectrum equation
TARG1		Coefficient of $\log f$
TARG2		Coefficient of $(\log f)^2$
TARG3		Coefficient of $(\log f)^3$

OUTPUT AND PLOT CONTROL CARDS

System

Name

OUTPT	Output data control parameter
SNPLT	Noise plot flag
HFLAG	Noise plot data card flag
SSPLT	Sound-speed profile plot flag

Three additional cards required after pause for noise plot

Title
Location
Date

Two additional cards required for sound-speed plot

Location
Date

INPUT DATA CONTROL CARDS

PAUSE	Used before each consecutive run except first
PRLOSS	Used before each prop loss array
END-DATA	Used at end of data or before plot cards that are at end of data

OUTPUTS

Plots

1. Noise level versus vertical arrival angle with or without target
2. Sound-speed profile

Table

Noise level versus vertical arrival angle
Target signal level versus vertical arrival angle
Total sector noise level

EXAMPLE COMPUTER RUN

Input

An example of a typical RANDI run follows to illustrate the input format and output products. In this example both a vertical directionality plot and a sound-speed profile

plot are requested. The input variables are sensor depth, frequency, latitude, wind speed, request for both plots, bottom loss versus grazing angle array and sound speed versus depth array. Three plot data cards are also included, giving the title, location, and date. All other parameters are automatically set equal to preprogrammed initial values.

Output

Figures B-2 through B-5 illustrate the output of RANDI for a given set of input data cards.

EXAMPLE OF HORIZONTAL DIRECTIONALITY

Shipping data for May 1, 1971, within a few hundred miles of the FLIP ambient noise measurement site, were utilized to illustrate the horizontal directionality capability of RANDI. To do this the noise field was divided into 36 horizontal pie-shaped sectors centered at the FLIP position. The vertical arrival structure of the noise field was obtained by running RANDI with different shipping distributions each time to get the average noise level every 10 deg. These levels were then reduced by 10 dB to get the per degree levels and plotted by a separate DISSPLA plot routine. Four of the 10-deg-horizontal-sector vertical directionality plots (Figs. B-8-11) have been included to demonstrate the variability in the vertical arrival structure.

MEMORANDUM FOR DISTRIBUTION LIST

Subj: DECLASSIFICATION OF LONG RANGE ACOUSTIC PROPAGATION PROJECT (LRAPP) DOCUMENTS

Ref: (a) SECNAVINST 5510.36

Encl: (1) List of DECLASSIFIED LRAPP Documents

1. In accordance with reference (a), a declassification review has been conducted on a number of classified LRAPP documents.
2. The LRAPP documents listed in enclosure (1) have been downgraded to UNCLASSIFIED and have been approved for public release. These documents should be remarked as follows:

Classification changed to UNCLASSIFIED by authority of the Chief of Naval Operations (N772) letter N772A/6U875630, 20 January 2006.

DISTRIBUTION STATEMENT A: Approved for Public Release; Distribution is unlimited.

3. Questions may be directed to the undersigned on (703) 696-4619, DSN 426-4619.
